Abstract

A scheme is presented and software is documented for representing as integers input decimal numbers that have been stored in a computer as double precision floating point numbers and for carrying out multiplications, additions and subtractions based on these numbers in an exact manner. The input decimal numbers must not have more than nine digits to the left of the decimal point. The decimal fractions of their floating point representations are all first rounded off at a prespecified location, a location no more than nine digits away from the decimal point. The number of digits to the left of the decimal point for each input number besides not being allowed to exceed nine must then be such that the total number of digits from the leftmost digit of the number to the location where round-off is to occur does not exceed fourteen.

1 Introduction

Mainstream computers base integer and floating point arithmetic on fixed word lengths. As a consequence, only values with a limited number of significant digits can be represented directly, so that the results of arithmetic operations may have to be rounded off or truncated. Such errors can be avoided or, at least, mitigated, by implementing special algorithms for the

execution of arithmetic operations. A fully 'exact arithmetic', however, would have to be based on quotients of integers for representing numerical values. In any case, a final limitation is due to finite memory.

The need for exact arithmetic became apparent during the development of software for generating triangular and tetrahedral nets from very large point sets. Typically, this need is not due to high accuracy requirements for results - the input data are often noisy or given up to only a few significant digits - but is rather due to the need to maintain the consistency of a combinatorial structure. Building or manipulating such geometry-based combinatorial structures requires the calculation of indicators such as determinants in order to evaluate their sign and to check for zero values: round-off may lead to a false sign or zero value. An example considered later in this paper is to decide whether four given spatial points are coplanar. The approach of using exact computations for implementing computational geometry algorithms in a robust manner has been addressed in [2], [3], [4], [5], [6], [7]. Some computational geometry implementations ([2], [3], [4], [5]) reduce computational effort by utilizing exact arithmetic selectively whenever a decision might be affected by round-off.

In this paper, we document software for exact integer arithmetic, accommodating an indeterminate number of digits, for multiplication, addition, subtraction, but excluding division. We found that, in many computational geometry applications, decision variables such as determinants can be calculated without division. Also the sign of a decision variable stated as a quotient but not evaluated is readily derived from the signs of the numerator and denominator.

We also describe a preprocessing step, called 'two-integer decomposition', which leads from floating point input to one composed of integers only. At the root of this step lies the concept of space as an integer grid of points, all of which have integer coordinates in some shared unit. After completing the transition from floating point numbers to intermediate representations as pairs of integers - prompted by the fact that Fortran 77 does not provide a double precision integer format - a 'polynomial decomposition' creates the number representations to be used in the exact arithmetic calculations. Software for this preprocessing step together with software for exact integer arithmetic has been successfully incorporated into several computational geometry related programs such as REGTET [1].

In what follows, a 'standard computer' is a computer that uses 64 bits of storage for a double precision number and 32 bits for an integer. Given a

standard computer, even though it may not store exactly an input decimal number as a double precision floating point number, it is safe to assume that the number will be represented as accurately as possible by a double precision floating point number up to its fourteenth significant digit.

2 Two-integer decomposition

Let x(i), i = 1, ..., n, be a double precision array into which input numbers x_i , i = 1, ..., n, have been read. The two-integer decomposition process is a preprocessing step that takes place before any computations based on the input data are carried out. It rounds off the numbers in the array at a prespecified location of their decimal fractions and decomposes each rounded off number into two integers that are saved in integer arrays, say ix(i), ix(i), i=1,...,n. The rounded off numbers are then saved in array x(i), i=1,...,n.

Given integers $k, l, 1 \le k \le 9, 0 \le l \le 9, k+l \le 14$, and assuming each input number x_i , i = 1, ..., n, has no more that k digits to the left of the decimal point, each number x(i), i = 1, ..., n, is rounded off at the l^{th} digit of its decimal fraction and decomposed into two integers in one of two ways according to its size. If the absolute value of x(i) times $(10.0d0)^{l}$ is less than $2^{30} (= 1073741824), x(i)$ is multiplied by $(10.0d0)^l$ and rounded off at the decimal point. The resulting integer is then placed in ix(i) while ix2(i) is set to zero. Finally, x(i) is redefined to be the double precision value of integer ix(i) divided by $(10.0d0)^l$. On the other hand, if the absolute value of x(i)times $(10.0d0)^l$ exceeds or equals 2^{30} , x(i) is truncated at the decimal point. The resulting integer (absolute value less than 2^{30} since $k \leq 9$) is placed in ix(i). In addition, the signed decimal fraction obtained by subtracting the double precision value of this integer from the initial value of x(i) is multiplied by $(10.0d0)^l$ and rounded off at the decimal point. The resulting integer (absolute value less than 2^{30} since $l \leq 9$) is placed in ix2(i). Next, x(i) is redefined to be the double precision value of integer ix(i) plus the value obtained by dividing the double precision value of integer ix2(i) by $(10.0d0)^{l}$. Finally, if the integer ix2(i) is zero then ix2(i) is set to 2^{30} so that ix2(i) is zero if and only if the initial absolute value of x(i) (before the two-integer decomposition process) times $(10.0d0)^l$ is less than 2^{30} .

The following is Fortran code for carrying out the two-integer decomposition process. Variables are either integer or double precision following

convention. It is noted that while some loss in precision may occur at the time the input numbers are read and transformed into double precision floating point numbers, some additional loss in precision may occur here as well when the decimal point in a number is shifted by dividing or multiplying it by a multiple of 10.0d0, when the signed decimal fraction of a number is obtained by truncating the number at its decimal point and subtracting the result from the initial value of the number, and when a number is rounded off with the two-integer decomposition process. However once the two-integer decomposition process is completed all computations that follow, exact and otherwise, are carried out in terms of the arrays x(i), ix(i), ix2(i), $i=1,\ldots,n$, under the assumption that for the purposes of the user for each $i, i=1,\ldots,n$, x(i) represents closely enough the input number x_i rounded off at the l^{th} digit of its decimal fraction, and an integer (not necessarily stored by the computer) in terms of ix(i) and ix2(i) represents closely enough the input number x_i times 10^l rounded off at the decimal point.

3 Polynomial decomposition

Given an integer l, $0 \le l \le 9$, let x_i , i = 1, ..., n, be input numbers whose double precision floating point representations have been rounded off at the l^{th} digit of their decimal fractions through the two-integer decomposition process. Let x(i), ix(i), ix(i), ix(i), $i=1,\ldots,n$ be the arrays produced by the two-integer decomposition process that contain the rounded off numbers and the two-integer decompositions. For each i, $i=1,\ldots,n$, an integer J(i,l) is symbolically defined as follows (its actual value is not necessarily computed or stored by the computer). If ix2(i) equals zero then J(i,l) is set equal to ix(i). If ix2(i) equals 2^{30} then J(i,l) is set equal to $ix(i) \cdot 10^l$. Finally, if ix2(i) is neither zero nor 2^{30} then J(i,l) is set to $ix(i) \cdot 10^l + ix2(i)$. In all cases for each i, $i = 1, \ldots, n$, J(i,l) is considered to approximate closely enough (for the purposes of the user) the input number x_i times 10^l rounded off at the decimal point.

Set M to 2^{15} . Given J(i,l), $1 \le i \le n$, the polynomial decomposition process is a procedure (presented below in the form of Fortran subroutine decmp2) that decomposes the integer J(i,l) into a unique collection of integers isga, isga in $\{-1,0,1\}$, ika, ika > 0, a_k , $0 \le a_k < M$, $k = 1, \ldots, ika$, such that J(i,l) equals $isga(\sum_{k=1}^{ika} a_k \cdot M^{k-1})$, isga the sign of J(i,l). Integers a_k , $k = 1, \ldots, ika$, are saved in an integer array, say ia(k), $k = 1, \ldots, ika$, and the collection of integers isga, ika, ia(k), $k = 1, \ldots, ika$, and the symbolic expression $isga(\sum_{k=1}^{ika} ia(k) \cdot M^{k-1})$ are then called, respectively, the polynomial decomposition and the symbolic polynomial representation of J(i,l), with isga as the sign of the representation. For each $i, i = 1, \ldots, n$, the poly-

nomial decomposition of the integer J(i,l) is identified each time an exact computation involving additions, subtractions, or multiplications is required that references the input number x_i . During one such computation, for each $i, 1 \leq i \leq n$, if the number x_i is referenced in the computation, once the polynomial decomposition of the corresponding integer J(i,l) is identified, each reference of x_i in the computation is replaced by the symbolic polynomial representation of J(i, l). The computation then takes effect as a sequence of additions, subtractions, or multiplications of symbolic polynomial representations with the final result being itself the symbolic polynomial representation of some integer. This final result can usually be used in only one of two ways. If it is known that for some positive integer m the integer that is equal to the final symbolic polynomial representation is approximately equal to the product of $(10^l)^m$ and the true value of the computation, then this integer is computed approximately as a double precision floating point number from its symbolic polynomial representation and the true value of the computation is then approximately obtained by dividing it by $((10.0d0)^l)^m$. On the other hand, if the purpose of the computation is simply that of obtaining the sign of the true result then the sign of the final symbolic polynomial representation is a satisfactory answer.

The concepts of polynomial decomposition and symbolic polynomial representation defined above for J(i,l), $1 \le i \le n$, can also be defined for any integer K (not necessarily stored by the computer) in the same manner. Accordingly, the following is a Fortran subroutine called decomp for finding the polynomial decomposition isga, ia(k), k = 1, 2, (ika is already known to equal 2) of an integer iwi (stored by the computer) with absolute value less than 2^{30} . Here mhalf equals $2^{15} (= 32768)$.

```
subroutine decomp(ia, isga, iwi, mhalf) integer ia(*), isga, iwi, mhalf, ivi if(iwi.gt.0) then isga = 1 ivi = iwi elseif(iwi.lt.0) then isga =-1 ivi = -iwi else isga = 0 ia(1) = 0
```

```
ia(2) = 0

return

endif

ia(2) = ivi/mhalf

ia(1) = ivi - ia(2)*mhalf

return

end
```

In particular if isclu is set to 10^l then isclu is less than 2^{30} (since $l \leq 9$) so that the polynomial decomposition isgu (equal to 1), iu(i), i = 1, 2, (iku is already known to equal 2) of isclu can be obtained by calling subroutine decomp with a Fortran instruction as follows.

```
call decomp(iu, isgu, isclu, mhalf)
```

Finally, the following is a Fortran subroutine called decmp2 for finding the polynomial decomposition isga, ika, ia(k), $k=1,\ldots,ika$, of the integer J(i,l), $1 \le i \le n$. Here iwi equals ix(i), iwi2 equals ix2(i), mhalf equals 2^{15} , mfull equals 2^{30} , and iu(k), k=1,2, is an array such that the polynomial decomposition of 10^l is iu(1), iu(2) (isgu and iku are already known to equal 1 and 2, respectively). In addition, it is assumed that subroutines mulmul and muldif (presented below) exist for multiplying and subtracting, respectively, two symbolic polynomial representations.

```
subroutine decmp2(ia, isga, ika, iwi, iwi2, mhalf, mfull, iu)
integer nkmax
parameter (nkmax=5)
integer ia(*), isga, ika, iwi, iwi2, mhalf, mfull, iu(*)
integer ie(nkmax), io(nkmax), isge, isgo, ike, iko, isgu, iku
call decomp(ia, isga, iwi, mhalf)
ika = 2
if(iwi2.ne.0) then
isgu = 1
iku = 2
call mulmul(ia, iu, ie, isga, isgu, isge, ika, iku,
ike, nkmax, mhalf)
if(iwi2.eq.mfull) iwi2 = 0
call decomp(io, isgo, iwi2, mhalf)
isgo = -isgo
```

4 Multiplying symbolic polynomial representations

Given the polynomial decompositions isga, ika, ia(k), k = 1, ..., ika, and isgb, ikb, ib(k), k = 1, ..., ikb, of two integers K_1 and K_2 , respectively, the following is a Fortran subroutine called mulmul that produces the polynomial decomposition isgo, iko, io(k), k = 1, ..., iko, of the integer $K_1 \cdot K_2$ by multiplying the symbolic polynomial representation of K_1 by that of K_2 (as polynomials) to produce a symbolic polynomial representation of $K_1 \cdot K_2$ from which the polynomial decomposition of $K_1 \cdot K_2$ can be obtained. Here nkmax is the dimension of the arrays ia, ib, io in the calling routine and mhalf equals 2^{15} . It is noted that the value of mhalf is of importance here since given integers $i, j, 1 \le i \le ika, 1 \le j \le ikb$, then $0 \le ia(i) < 2^{15}, 0 \le ib(j) < 2^{15}$, so that the product $ia(i) \cdot ib(j)$ is less than 2^{30} and therefore can be stored in a 32 bit integer word.

```
subroutine mulmul(ia, ib, io, isga, isgb, isgo, ika, ikb, iko,

* nkmax, mhalf)

integer ia(*), ib(*), io(*)

integer isga, isgb, isgo, ika, ikb, iko, nkmax, mhalf

integer i, ipt, ipr, iko1, k, j

if(isga.eq.0.or.isgb.eq.0)then

isgo=0

iko = 2

io(1) = 0

io(2) = 0

return

endif

iko = ika + ikb

if(iko.gt.nkmax) stop 110
```

```
if(isga.gt.0)then
        if(isgb.gt.0)then
            isgo = 1
        else
            isgo = -1
        \operatorname{endif}
    else
        if(isgb.gt.0)then
            isgo = -1
        else
            isgo = 1
        endif
    endif
    iko1 = iko - 1
    ipr = 0
    do 200 i = 1, iko1
        ipt = ipr
        k = i
        do 180 j = 1, ikb
            if(k .lt. 1) go to 190
            if(k .gt. ika) go to 150
            ipt = ipt + ia(k)*ib(j)
150
            continue
            k = k - 1
180
        continue
190
        continue
        ipr = ipt/mhalf
        io(i) = ipt - ipr*mhalf
200 continue
    io(iko) = ipr
    if(ipr.ge.mhalf) stop 120
    iko1 = iko
    do 300 i = iko1, ika+1, -1
        if(io(i) .ne. 0) go to 400
        iko = iko - 1
300 continue
400 continue
    return
```

5 Subtracting symbolic polynomial representations

Given the polynomial decompositions isga, ika, ia(k), $k=1,\ldots,ika$, and isgb, ikb, ib(k), $k=1,\ldots,ikb$, of two integers K_1 and K_2 , respectively, the following is a Fortran subroutine called muldif that produces the polynomial decomposition isgo, iko, io(k), $k=1,\ldots,iko$, of the integer K_1-K_2 by subtracting the symbolic polynomial representation of K_2 from that of K_1 (as polynomials) to produce a symbolic polynomial representation of K_1-K_2 from which the polynomial decomposition of K_1-K_2 can be obtained. Here nkmax is the dimension of the arrays ia, ib, io in the calling routine and mhalf equals 2^{15} . It is noted that by setting isgb equal to -isgb the polynomial decomposition of K_1+K_2 can also be obtained with this subroutine.

```
subroutine muldif(ia, ib, io, isga, isgb, isgo, ika, ikb, iko,
                          nkmax, mhalf)
    integer ia(*), ib(*), io(*)
    integer isga, isgb, isgo, ika, ikb, iko, nkmax, mhalf
    integer i, iko1, irel
    if(isgb.eq.0)then
        if(isga.eq.0)then
           isgo=0
           iko = 2
           io(1) = 0
           io(2) = 0
           return
        endif
        isgo = isga
        iko = ika
        do 100 i=1,iko
            io(i) = ia(i)
100
        continue
    elseif(isga.eq.0)then
        isgo = -isgb
        iko = ikb
```

```
do 200 i=1,iko
           io(i) = ib(i)
200
        continue
    else
        iko = ika
        if(ikb.lt.ika) then
           do 300 i=ikb+1,ika
               ib(i) = 0
300
           continue
        elseif(ika.lt.ikb) then
           iko = ikb
           do 400 i=ika+1,ikb
               ia(i) = 0
400
           continue
        endif
        if(isga*isgb.gt.0)then
           irel = 0
           do 500 i = iko, 1, -1
               if(ia(i).gt.ib(i))then
                   irel = 1
                   go to 600
               elseif(ia(i).lt.ib(i))then
                   irel = -1
                   go to 600
               endif

6 Application: locating a point relative to a plane

Given an integer $n, n \ge 4$, let S be a set of n points in 3-dimensional space. Given an integer $l, 0 \le l \le 9$, let $x_i, y_i, z_i, i = 1, ..., n$, be the input decimal coordinates of the points in S, and assume that their double precision floating point representations have been rounded off at the l^{th} digit of their decimal fractions through applications, one per coordinate, of the two-integer decomposition process. Accordingly, let x(i), ix(i), ix(i), ix(i), iy(i), iy(i), iy(i), z(i), iz(i), iz(i),

Given points p_1 , p_2 , p_3 in S that are vertices of a non-degenerate triangle, a fundamental problem in computational geometry is that of finding the location of a point p_4 in S relative to the plane H that contains the triangle. Let H^+ be the open half-space defined by H for which p_1 , p_2 , p_3 appear in a counterclockwise direction around the boundary of the triangle when looking at the triangle from H^+ . Let H^- be the other half-space defined by H. Determining in which of H, H^+ , H^- , the point p_4 is located may not on occasion be satisfactorily done using floating point arithmetic. Accordingly, the following is a Fortran subroutine called crsinn for doing this using polynomial decompositions. On output the sign isgo (-1, 0, 1) of some polynomial decomposition determines the location of p_4 (H^- , H, H^+).

This routine actually does more. It produces polynomial decompositions isgox, ikox, iox(k), k = 1, ..., ikox, isgoy, ikoy, ioy(k), k = 1, ..., ikoy, isgoz, ikoz, ioz(k), k = 1, ..., ikoz, of integers that are the coordinates of a vector v pointing into H^+ and perpendicular to H. It also produces the polynomial decomposition isgo, iko, io(k), k = 1, ..., iko, of an integer whose sign isgo determines the location of p_4 and whose value when divided by both 10^l and the length of v is the perpendicular distance from p_4 to H. Here mhalf equals 2^{15} , mfull equals 2^{30} , and ifir, isec, ithi, ifou are locations in the arrays ix, ix2, etc. corresponding to the points p_1 , p_2 , p_3 , p_4 , respectively. In addition, isclp(k), k = 1, 2, is an array such that the polynomial decomposition of 10^l is isclp(1), isclp(2) (the sign of 10^l and the dimension of array isclp are already known to be 1 and 2, respectively).

Sometimes besides knowing the location of the point p_4 relative to the plane H it may be desirable to know the perpendicular distance from p_4 to H. The following is Fortran code for this purpose. It uses the polynomial decompositions that are part of the output of subroutine crsinn. Variables here are either integer or double precision following convention. Here r215 equals $(2.0d0)^{15}$, dscle equals $(10.0d0)^l$, and dist is the resulting signed perpendic-

ular distance. In addition, it is assumed that subroutine doubnm (presented below) exists for transforming the polynomial decomposition of an integer into the double precision floating point value of the integer.

```
call crsinn(ix, iy, iz, ix2, iy2, iz2, ifir, isec, ithi, ifou,
               mhalf, mfull, isclp, io, isgo, iko, iox, isgox,
               ikox, ioy, isgoy, ikoy, ioz, isgoz, ikoz)
   call doubnm(io, isgo, iko, r215, dnum)
   call doubnm(iox, isgox, ikox, r215, xnum)
   call doubnm(ioy, isgoy, ikoy, r215, ynum)
   call doubnm(ioz, isgoz, ikoz, r215, znum)
   dnux = dmax1(dabs(xnum), dabs(ynum), dabs(znum))
   xnum = xnum/dnux
   vnum = vnum/dnux
   znum = znum/dnux
   dnom = dsqrt(xnum^{**}2+ynum^{**}2+znum^{**}2)
   dist = ((dnum/dnux)/dnom)/dscle
The following is subroutine doubnm that was called above.
   subroutine doubnm(io, isgo, iko, r215, dnum)
   integer io(*)
   double precision dnum, r215, rpwr
   integer isgo, iko, i
   if(isgo.eq.0) then
      dnum = 0.0d0
      go to 900
   else
      if(iko .lt. 2) stop 310
      if(iko .gt. 68) stop 320
      rpwr = 1.0d0
      dnum = dble(io(1))
      do 100 i = 2, iko
```

rpwr = rpwr*r215

if(isgo.lt.0) dnum = -dnum

continue

100

endif

900 continue

dnum = dnum + dble(io(i))*rpwr

return end

7 Numerical examples

Twelve lines follow, each line containing three numbers. Each line corresponds to a point in 3-dimensional space, and the three numbers in the line correspond to the x-, y-, z-coordinates of the point, in that order. Given i, $1 \le i \le 12$, point i is the point corresponding to the i^{th} line. It is assumed that the coordinates of the twelve points are read into double precision arrays x(i), y(i), z(i), $i = 1, \ldots, 12$, so that x(i), y(i), z(i) contain the x-, y-, z-coordinates, respectively, of point i.

Given l equal to 8, through the two-integer decomposition process, the numbers above are rounded off at the $l^{th} = 8^{th}$ digit of their decimal fractions and saved in x(i), y(i), z(i), $i = 1, \ldots, 12$, so that then they appear as follows.

```

Each rounded off coordinate is also decomposed into two integers. Twelve lines follow, each line containing six integers. For each i, i = 1, ..., 12, the first two integers in the i^{th} line are the two integers into which the x-coordinate of point i is decomposed. Similarly the next two integers correspond to the y-coordinate, and the last two to the z-coordinate. The two-integer decompositions of the twelve points are then saved into ix(i), ix2(i), iy(i), iy2(i), iz(i), iz2(i), $i=1,\ldots,12$, in the obvious manner. It is noted that when $mfull=2^{30}=1073741824$ appears as the second integer corresponding to a coordinate it is to be interpreted as a zero.

Given l as above equal to 8 and setting isclu to $10^l = 10^8$, by calling subroutine decomp the polynomial decomposition of isclu is found to be isgcl, isclp(1), isclp(2), with isgcl equal to 1, isclp(1) equal to 24832 and isclp(2) equal to 3051 ($10^8 = 24832 + 3051 \cdot mhal f = 24832 + 3051 \cdot 2^{15}$).

As an example of how exact computations are carried out that reference coordinates of the input points given above, the computation that is the product of the x-coordinate of point 2 and the y-coordinate of point 4 minus the product of the y-coordinate of point 2 and the x-coordinate of point 4 is described. Using rounded-off numbers the result of the computation should equal $x(2) \cdot y(4) - y(2) \cdot x(4)$, i. e.

```
(38.000000000) \cdot (-49.840807040) - (7.049967880) \cdot (85.557213020).
```

On the other hand, if exact computations are required then each of the four numbers involved must first be converted into an integer which is the number times 10⁸ rounded off at the decimal point. Since the resulting integer may be too big to be saved into a 32 bit integer word, its polynomial decomposition in the form of two or more 32 bit integer words is obtained instead. Thus, for example, the polynomial decomposition of the integer which is the x-coordinate of point 4 times 10^8 rounded off at the decimal point can be obtained by calling subroutine decmp2 using the two-integer decomposition of the coordinate, i. e. the integers 85 and 55721302, and the polynomial decomposition of 10⁸ as obtained above. The resulting polynomial decomposition is then found to be isgox4, ikox4, iox4(k), k = 1, ..., ikox4, with isgox4 equal to 1, ikox4 equal to 3, iox4(k), k=1,2,3, equal to 29270, 31723, and 7 (the integer which is the x-coordinate of point 4 times 10^8 rounded off at the decimal point equals $29270 + 31723 \cdot (2^{15}) + 7 \cdot (2^{15})^2$. In the same manner the polynomial decompositions associated with the x-, y-coordinates of point 2, and the y-coordinate of point 4 are found to be, respectively, isgox2, ikox2, iox2(k), $k = 1, \ldots, ikox2$, isgoy2, ikoy2, ioy2(k), $k = 1, \dots, ikoy2, isgoy4, ikoy4, ioy4(k), k = 1, \dots, ikoy4, with isgox2$ equal to 1, ikox2 equal to 3, iox2(k), k = 1, 2, 3, equal to 26112, 17662, 3, isgoy2equal to 1, ikoy2 equal to 2, ioy2(k), k = 1, 2, equal to 26036, 21514, isgoy4equal to -1, ikoy4 equal to 3, ioy4(k), k = 1, 2, 3, equal to 2368, 21030, 4. Finally, using these polynomial decompositions as input the desired result is obtained by calling subroutines mulmul and muldif as follows. Here nkmaxis the dimension of all of the arrays (input and output).

call mulmul(iox2,ioy4,iu,isgox2,isgoy4,isgu,ikox2,ikoy4,iku,nkmax,mhalf) call mulmul(ioy2,iox4,iv,isgoy2,isgox4,isgv,ikoy2,ikox4,ikv,nkmax,mhalf) call muldif(iu,iv,io,isgu,isgv,isgo,iku,ikv,iko,nkmax,mhalf)

The polynomial decomposition of an integer that approximates the desired result times $(10^8)^2$ rounded off at the decimal point is then found to be isgo, iko, io(k), k = 1, ..., iko, with isgo equal to -1, iko equal to 5, io(k), k = 1, ..., 5, equal to 21112, 15183, 31880, 21597, 21. The desired result is then approximately equal to this integer, i. e. $21112 + 15183 \cdot (2^{15}) + 31880 \cdot (2^{15})^2 + 21597 \cdot (2^{15})^3 + 21 \cdot (2^{15})^4$, divided by $(10^8)^2$. By calling subroutine doubnm the integer can be approximated by a double precision number which when divided by $(10^8)^2$ is approximately -2497.1262712133, an approximation of the desired result.

Finally, an example is given for the purpose of decribing the process of locating a point relative to a plane that contains three other points. Here the point whose location is desired is point 12 as given above, and the three other points are point 1, point 2, point 8 also as given above. With t as the triangle with vertices point 1, point 2, point 8, and H as the plane that contains t, H^+ is taken to be the open half-space defined by H for which point 1, point 2, point 8 appear in a counterclockwise direction around the boundary of t when looking at t from H^+ . H^- is taken to be the other half-space defined by H. With ifir set to 1, isec set to 2, ithi set to 8, ifou set to 12, which of H, H^+ , H^- contains point 12 can be determined by calling subroutine crsinn as follows.

```
call crsinn(ix, iy, iz, ix2, iy2, iz2, ifir, isec, ithi, ifou,

* mhalf, mfull, iselp, io, isgo, iko, iox, isgox,

ikox, ioy, isgoy, ikoy, ioz, isgoz, ikoz)
```

On output isqo equals -1 so that point 12 must be in H^- . In addition iko equals 7, io(k), k = 1, ..., 7, equals 21844, 27853, 3870, 5372, 13630, 9887, 213, isgox equals -1, ikox equals 5, iox(k), k = 1, ..., 5, equals 11868, 15341, 2677, 15631, 62, isgoy equals 1, ikoy equals 5, ioy(k), $k = 1, \ldots, 5$, equals 11577, 8756, 364, 27887, 63, isgoz equals -1, ikoz equals 5, ioz(k), $k = 1, \ldots, 5$, equals 5921, 23919, 26934, 16812, 19. By calling subroutine doubnm the integer whose polynomial decomposition is isgo, iko, io(k), $k=1,\ldots,iko$, can be approximated by a double precision number dnum. Similarly, the three integers, say ix, iy, iz, whose polynomial decompositions are isgox, ikox, iox(k), $k = 1, \ldots, ikox$, isgoy, ikoy, ioy(k), $k = 1, \ldots, ikoy$, $isgoz, ikoz, ioz(k), k = 1, \dots, ikoz,$ can be approximated, respectively, by double precision numbers xnum, ynum, znum. The vector (ix, iy, iz), which is perpendicular to the plane H and points into H^+ , can then be approximated by the vector (xnum, ynum, znum). Finally, by dividing dnum by both the length of the vector (xnum, ynum, znum) and 10^8 the number -25.047402554921 is approximately obtained, an approximation of the signed perpendicular distance from point 12 to plane H, the negative sign indicating that point 12 is in H^- .

8 Summary

A scheme has been presented and software has been documented for transforming into a series of integers input decimal numbers that have been read into a computer as double precision floating point numbers and for carrying out multiplication, addition and subtraction operations based on these numbers using their integer representations. The total number of significant digits of each input number must not be greater than 14, and the number of digits to the left of the decimal point must not exceed 9. Through a preprocessing step the double precision floating point representation of each input decimal number is rounded off at a prespecified location of its decimal fraction, a location no more than 9 digits to the right of the decimal point, and the rounded off number is decomposed into two integers. All operations that follow involving the input number are then carried out in terms of the rounded off double precision floating point number and when this is not satisfactory in terms of the two integers. This scheme has been successfully incorporated into several computational geometry related programs such as REGTET [1]. Other programs that incorporate this scheme can be found at http://math.nist.gov/~JBernal/JBernal_Sft.html. Besides being used for locating a point relative to a plane, in these programs the scheme has also been used for locating a point relative to a sphere, for computing the intersection of a line and a plane, for computing the center of a sphere, etc.
